ABSTRACT—A three-level converter is used as the power converters of wind turbine systems because of their advantages such as low-current total harmonic distortion, high efficiency, and low collector–emitter voltage. Interior permanent magnet synchronous generators (IPMSGs) have been chosen as the generator in wind turbine systems owing to their advantages of size and efficiency. In wind turbine systems consisting of the three-level converter and the IPMSG, fault-tolerant controls for an open-circuit fault of switches should be implemented to improve reliability. This paper focuses on the open-circuit fault of outer switches (Sx1andSx4) in three level rectifiers (both neutral-point clamped and T-type) that are connected to the IPMSG. In addition, the effects ofSx1 andSx4 open-circuit faults are analyzed, and based on this analysis, a tolerant control is proposed. The proposed tolerant control maintains normal operation with sinusoidal currents under the open-circuit fault of outer switches by adding a compensation value to the reference voltages. The effectiveness and performance of the proposed tolerant control are verified by simulation and experiment.

I. INTRODUCTION

The power capacity of a wind turbine system has been increasing consistently, leading to the development of generators with large power capacity [1]–[3]. There are many types of generators. Permanent magnet synchronous generators (PMSGs) have high efficiency and high reliability compared with induction generators. This is because external excitation is not required and there are no copper losses in the rotor circuits. Moreover, because of the smaller size of the PMSG, the weight of the wind turbine is reduced [4].

Among various PMSGs, interior PMSGs (IPMSGs) are especially advantageous from the standpoints of efficiency and power generation owing to the use of the reluctance torque [4]–[7]. Generators requiring high voltage need to use multilevel converter topologies to reduce the collector–emitter voltage per switch. Among multilevel topologies, three-level topologies such as the three-level neutral-point clamped (3L-NPC) and T-type topologies are applied in wind turbine systems with a wide power range. The three-level topology can easily be expanded from a two-level topology and is also easier to control compared with other multilevel topologies.

Furthermore, the three-level topology guarantees high efficiency and low-current total harmonic distortion (THD) in comparison with the two level topology [8]–[11]. The 3L-NPC topology is vulnerable to switch faults because many switches are used. Switch fault detection and tolerant control methods for switch faults should be implemented to improve the reliability of wind turbine systems. Switch faults are divided into a short-circuit fault and an open-circuit fault [12]. The short-circuit fault normally leads to a breakdown of the entire system; therefore, fault detection and tolerant control methods for the short-circuit fault require additional circuits. A back-to-back converter using the 3L-NPC topology is shown in Fig. 1.

Fig. 1. Back-to-back converter using the 3L-NPC topology in wind turbine systems.

This consists of the machine-side 3L-NPC rectifier, the dc-link, and the grid-side 3L-NPC inverter. Depending on the operating conditions, tolerant controls can be applied for the rectifier or the inverter because the current paths of the rectifier and the inverter are different [9], [13]–[15]. In addition, the different structure of the three-level topologies should be considered in the tolerant controls [9], [13]. In the 3L-NPC inverter, the open-circuit fault of the inner switch causes the outer switch connected it to be infeasible; therefore, changing only the switching method does not become a solution for the open-circuit fault, and the additional devices such as fuses and switches should be added for achieving the
tolerant operation under the open-circuit fault of the inner switch [16]–[18].

However, the open-circuit fault of the outer switch can be handled by changed the switching method in limited range [19]. In [19], the tolerant control method limits the output voltage range by half. In addition, the reactive current is injected to eliminate current distortion caused by the open-circuit fault of the outer switch [22].

when rectifiers operate at a unique pf [4]–[7].

In such a case, an open-circuit fault of the outer switches (Sx1 and Sx4) causes current distortion and torque fluctuation, which can lead to vibration of the wind turbine. In this paper, the reason for the current distortion caused by the outer switches (Sx1 and Sx4) is analyzed, and then, on the basis of this analysis, a tolerant control for Sx1 and Sx4 open-circuit faults is proposed.

### III. OPEN-CIRCUIT FAULT ANALYSIS OF OUTERSWITCHES

There are three switching states (P, N, and O) in the 3L-NPC rectifier [9]. Six current paths can be generated depending on the current direction and the switching state, and these are shown in Fig. 2 [23]. Fig. 3 shows the input current generation process of a rectifier with unity pf.

The phase difference between VEMF and Vrec, which causes the current flow, is controlled to match the phase of the corresponding VEMF. One period of Irec can be divided into four parts depending on the polarity of Irec and Vrec. The generated current paths are different depending on the part, and these are summarized in Table I. In parts A and C, the O switching state causes the input current flow; therefore, this is called the valid switching state. The current continuously flows through two diodes if the switching state is changed to P or N switching state in which no current flows through the switches.

In parts B and D, the P and N switching stages are the valid switching state where the current flows through the switches. When the rectifier operates with unity pf, parts A and C are large, and parts B and D are small.

In this paper, the other case (Case II), which is the reactive current injection for IPMSG, is also considered. Fig. 4 shows that the input current generation process of the rectifier for Cases I and II. There are two phase differences: the phase difference ($\phi_Z$) between VEMF and Vrec explained in [22], and the phase difference ($\phi_{pf}$) between Iref and VEMF caused by the pf. In Fig. 4, part B (or part D) consists of $\phi_Z$ and $\phi_{pf}$, and their lengths increase. This means that the current can be more distorted by the open-circuit fault of the outer switches compared to when $\phi_Z$ alone is considered.
Case I can be ignored because $\phi Z$ is determined depending on the operating condition of the rectifier and the PMSG. However, because $\phi pf$, Case II should be considered when the IPMSG is employed. The current distortion caused by the open-circuit fault of the outer switches is shown in Fig. 5 for various $\phi pf$. Owing to the infeasible open-circuit fault switch, the current becomes zero during the range consisting of $\phi Z$ and $\phi pf$. The $Sx1$ open-circuit fault makes the current path of Fig. 2(d) infeasible.

The current path of Fig. 2(d) belongs to part B; therefore, the $Sx1$ open-circuit fault causes distortion in the negative current as shown in Fig. 5(a) and (c). On the contrary, the $Sx4$ open-circuit fault leads to distortion in the positive current as shown in Fig. 5(b) and (d) because the current path of Fig. 2(c) related to the $Sx4$ open-circuit fault belongs to part D. The low power factor has a large $\phi pf$. Therefore, the rectifier operation at a low power factor leads to a large zero-current range when the open-circuit fault of the outer switch occurs. As a result, the zero-current range increases, as the pf decreases.

An existing tolerant control method for the open-circuit fault of the outer switches is reactive current injection [22]. This method changes the phase of $I_{recs}$ so that it corresponds with the phase of $V_{rec}$. This means that parts B and D are eliminated. However, this tolerant control method has the disadvantage of low-power generation efficiency of the generator because the PMSG has efficient operating condition which depends on the pf of the rectifier. The proposed tolerant control does not change the pf of the rectifier. The rectifier voltage ($V_{rec}$) without the current path related to the open-circuit fault switch is generated by changing the reference voltages. To explain the proposed tolerant control, the $Sx1$ open-circuit fault is used as an example.

**A. Compensation Voltage ($V_{comp}$) Calculation**

Three-phase reference voltages ($V_{x, ref}$, $x=a, b, c$) are expressed as

$$V_{a, ref} = V_{mag} \cos(2\pi f_1 t)$$
$$V_{b, ref} = V_{mag} \cos(2\pi f_1 t - 2\pi / 3)$$
$$V_{c, ref} = V_{mag} \cos(2\pi f_1 t + 2\pi / 3)$$

Where $V_{mag}$ is the magnitude of the reference voltages, and $f_1$ is the fundamental frequency. The offset voltage ($V_{offset}$) is added to each reference voltage to expand the range of the modulation index ($M_a = \sqrt{3} \times V_{mag}/V_{dc}$). $V_{offset}$ and the changed reference voltages ($V_{x, ref, offset}$, $x=a, b, c$) are expressed as

$$V_{offset} = \frac{V_{ref, max} + V_{ref, min}}{2}$$
$$V_{a, ref, offset} = V_{a, ref} + V_{offset}$$
$$V_{b, ref, offset} = V_{b, ref} + V_{offset}$$
$$V_{c, ref, offset} = V_{c, ref} + V_{offset}$$

Where $V_{ref, max}$ and $V_{ref, min}$ are the maximum and minimum values of $V_{a, ref}, V_{b, ref},$ and $V_{c, ref}$. The reference voltages of (3) are compared with the carrier signals to generate $V_{rec}$. When the $Sx1$ open-circuit fault occurs, the current path of Fig. 2(d) should be eliminated to prevent current distortion; therefore, the reference voltage should be changed to generate $V_{rec}$ without the current path of Fig. 2(d). In the proposed tolerant control, a reference voltage of a phase containing the $Sx1$ open-circuit fault is changed to zero as shown in Fig. 6. As a result, the current path of Fig. 2(d) disappears because the O switching state is only used in part B. To make the reference voltage zero, $|V_{comp}|$ is assigned the magnitude of the reference voltage ($V_{x, ref, offset}$) containing the open-circuit fault, and $V_{comp}$ can be expressed as

![Fig. 5. Current distortion depending on the open-circuit fault and the power factor.](image-url)
The proposed tolerant control is implemented by adding $V_{comp}$ to the reference voltages ($V_{x,\text{ref, offset}}$, $x=a, b, c$). The new reference voltages ($V_{x,\text{ref, tolerance}}$, $x=a, b, c$) of the proposed tolerant control are expressed as

$$V_{a,\text{ref, tolerance}} = V_{a,\text{ref, offset}} + V_{\text{comp}}$$
$$V_{b,\text{ref, tolerance}} = V_{b,\text{ref, offset}} + V_{\text{comp}}$$
$$V_{c,\text{ref, tolerance}} = V_{c,\text{ref, offset}} + V_{\text{comp}}$$

### B. Compensation Range for Adding $V_{\text{comp}}$

By adding $V_{\text{comp}}$ to each reference voltage, the use of the current path related to the open-circuit fault switch will be precluded. To achieve this perfectly, $V_{\text{comp}}$ is added for the suitable range and position. The compensation range, which is part B or part D of Fig. 4, consists of $\phi_Z$ and $\phi_{pf}$. $\phi_Z$ can be calculated with the equivalent circuit of the PMSG and the three-level rectifier [22]. $\phi_Z$ is the phase difference between VEMF and Vrec, is expressed as

$$\phi_Z = \tan^{-1}\left(\frac{-|I_{\text{rec}}|2\pi f_s}{|V_{\text{EMF}}| |V_{\text{ref}}| |R|} \right)$$

(6)

where $R$ and $L$ are the equivalent resistance and inductance of the PMSG, and $f_s$ is the fundamental frequency representing the angular frequency of the PMSG. $\phi_{pf}$, which is the phase difference between VEMF and Irec, is related to the pf. $\phi_{pf}$ can be calculated by the pf and this is expressed as

$$\phi_{pf} = \cos^{-1}(pf)$$

(7)

If the d–q control theorem is used, $\phi_{pf}$ can be calculated as

$$\phi_{pf} = \cos^{-1}\left(\frac{i_q}{\sqrt{i_d^2+i_q^2}}\right)$$

(8)

Where $I_d$ indicates the d-axis current related to the flux and $I_q$ indicates the q-axis current related to the torque, and these values are in the d–q synchronous rotating frame. $\phi_Z$ and $\phi_{pf}$, which are calculated from (6) and (8), are located near the zero-crossing point of VEMF as shown in Fig. 6. Therefore, the compensation position for adding $V_{\text{comp}}$ is defined on the basis of VEMF’s angle ($\theta_{\text{EMF}}$).
C. Considering Neutral-Point Voltage Balance

The compensation voltage which is one of the offset voltages can cause neutral-point voltage unbalance because $V_{\text{comp}}$ calculated from (4) is a one-sided voltage.

Fig. 8 shows the concept of proposed tolerant control considering the neutral-point voltage balance when the $S_{a1}$ open-circuit fault occurs. In Fig. 8, $V_{\text{comp}}$ is added for the compensation range $[(0^\circ - \phi_{pf}) \sim (0^\circ + \phi_{Z})]$ which corresponds to the position for the $S_{a1}$ open-circuit fault; in addition, $V_{\text{comp}}$ is also added for the diametrically opposite compensation range $[(180^\circ - \phi_{pf}) \sim (180^\circ + \phi_{Z})]$, which is the range for the $S_{a4}$ open-circuit fault. The final principles of the proposed tolerant control with the neutral-point voltage balance are summarized in Table III.

D. Limitation of Proposed Tolerant Control

$V_{\text{x,ref,tolerance}}$ cannot exceed a limitation voltage ($V_{\text{limit}}$) which is restricted by the dc-link voltage ($V_{\text{dc}}$). Therefore, $V_{\text{comp}}$ is limited as follows

$$V_{\text{comp}} < V_{\text{limit}} - V_{\text{ref,max}}$$

Where $V_{\text{limit}}$ is $V_{\text{dc}}/2$. On the basis of (9), the applicable operation range of the proposed tolerant control is determined depending on $M_a$ and $\phi_{pf}$. Fig. 9 shows $V_{\text{x,ref,tolerance}}$ and $V_{\text{comp}}$ depending on $\phi_{pf}$ when $M_a$ is 0.5. In Fig. 9, $V_{\text{comp}}$ leads to $V_{\text{x,ref,tolerance}}$ with zero value in the corresponding compensation range. Moreover, the peak value of $V_{\text{c,ref,tolerance}}$, $V_{\text{c,ref,tolerance}}$, increases owing to $V_{\text{comp}}$.

As the $\phi_{pf}$ decreases, this peak value increases; however, it does not exceed $V_{\text{limit}}$. Consequently, when $M_a$ is smaller than 0.5, $V_{\text{comp}}$ can be added regardless of $\phi_{pf}$ because $V_{\text{c,ref,tolerance}}$ cannot exceed $V_{\text{limit}}$. When $M_a$ is larger than 0.5, the applicable operation range is determined by $M_a$. This is because a low $M_a$ provides a large margin for $V_{\text{comp}}$; however, a large $V_{\text{comp}}$ cannot be acceptable for high $M_a$. Fig. 10 shows the applicable operation range for various values of $M_a$. The shaded part of Fig. 10 represents the applicable operation range. The proposed tolerant control is feasible over the entire factor range when $M_a$ is smaller than 0.5. By increasing $M_a$ from 0.5, the applicable operation range decreases.

</tbody>
</table>
Fig. 10. Applicable pfrange of the proposed tolerant control depending on $Ma$

In Fig. 10, the applicable operation range shown as ARpf is largest when only the pf related to $\phi_{pf}$ is taken into account. However, a large $\phi_{Z}$ means that large portion of the compensation range is reserved for $\phi_{Z}$, and the rest can be used to compensate $\phi_{pf}$.

IV. SIMULATION RESULTS

The simulation is performed using the PSIM tool. The 3L-NPC rectifier of the back-to-back converter with 2.5-MW IPMSG is only considered in the simulation. Fig. 11 shows the simulation results of the proposed tolerant control when the Sa1 open-circuit fault occurs. The speed.

</tbody>
</table>

As a result, the a-phase pole voltage (Van) is clamped to 0 at their ranges as shown in Fig. 11(b) and the current distortion is eliminated completely.

In addition, the two dc-link capacitor voltages are balanced. The proposed tolerant control is effective for the pf transition operation of the rectifier. Fig. 12 shows the results when the proposed tolerant control is applied and the pf is changed from 0.95 to 0.9.

![Simulation results with the proposed tolerant control under the Sa1 open-circuit fault (600 rpm, $Ma = 0.35, pf$-transition from 0.95 to 0.9).](image)

Fig. 13 shows the performance of the proposed tolerant control under the Sa1 open-circuit fault at different speed (1000 rpm) of the PMSG when $Ma$ is 0.59. Similar to Fig. 11, the distorted currents are corrected after the proposed tolerant control is applied. However, the peak value of $V_{c,ref}$ tolerance is close to $V_{\text{limit}}(V_{dc}/2)$ at 0.95 pf, which is different from what is shown in Fig. 11. This is because $Ma$ of Fig. 13 has a smaller.
Fig. 13. Simulation results with the proposed tolerant control under the Sa1 open-circuit fault (1000 rpm, Ma = 0.59, 0.95 pf)

Table V shows the current THD results before and after the proposed tolerant control is applied. The current THD is increased by the Sa1 open-circuit fault; however, owing to the proposed tolerant control, the current THD is restored as good as normal state without any open-circuit fault.

VI. CONCLUSION

This paper proposes a tolerant control for the open-circuit fault of the outer switches in three-level rectifiers (both 3L-NPC and T-type topologies) used in wind turbine systems. The reason why the tolerant control for the open-circuit fault of the outer switches in three-level rectifiers is necessary is presented, together with the supporting circuit analysis. On the basis of the analysis, a tolerant control for each open-circuit fault is proposed that takes into account the neutral-point voltage balance. This control is implemented by adding a compensation voltage (Vcomp) to the reference voltages for the corresponding compensation ranges depending on the position of the open-circuit fault. Furthermore, this control can be used in both the 3L-NPC and T-type rectifiers and guarantees normal operation without a change of the pf in the applicable operation range shown in Fig. 10 depending on the modulation index (Ma) and the pf. Although the operating range of the proposed tolerant control is subject to a limitation, considering that wind turbine systems do not always operate with the rated wind speed and that the operating pf of the rectifier with an IPMSG is not too low, the proposed tolerant control is clearly effective. The performance and effectiveness of the proposed tolerance control are proved through simulations.
